Abstract

*TreatJS* is a language embedded, higher-order contract system for JavaScript which enforces contracts by run-time monitoring. Beyond providing the standard abstractions for building higher-order contracts (base, function, and object contracts), *TreatJS*’s novel contributions are its guarantee of non-interfering contract execution, its systematic approach to blame assignment, its support for contracts in the style of union and intersection types, and its notion of a parameterized contract scope, which is the building block for composable run-time generated contracts that generalize dependent function contracts.

*TreatJS* is implemented as a library so that all aspects of a contract can be specified using the full JavaScript language. The library relies on JavaScript proxies to guarantee full interposition for contracts. It further exploits JavaScript’s reflective features to run contracts in a sandbox environment, which guarantees that the execution of contract code does not modify the application state. No source code transformation or change in the JavaScript run-time system is required. The impact of contracts on execution speed is evaluated using the Google Octane benchmark.

Keywords and phrases Higher-Order Contracts, JavaScript, Proxies

1 Introduction

A contract specifies the interface of a software component by stating obligations and benefits for the component’s users. Customarily contracts comprise invariants for objects and components as well as pre- and postconditions for individual methods. Prima facie such contracts may be specified using straightforward assertions. But further contract constructions are needed for contemporary languages with first-class functions and other advanced abstractions. These facilities require higher-order contracts as well as ways to dynamically construct contracts that depend on run-time values.

Software contracts were introduced with Meyer’s *Design by Contract™* methodology [41] that stipulates the specification of contracts for all components of a program and the monitoring of these contracts while the program is running. Since then, the contract idea has taken off and systems for contract monitoring are available for many languages [35, 1, 38, 34, 13, 23, 11, 10] and with a wealth of features [37, 33, 7, 21, 48, 17, 2]. Contracts are particularly important for dynamically typed languages as these languages only provide memory safety and dynamic type safety. Hence, it does not come as a surprise that the first higher-order contract systems were devised for Scheme and Racket [25], out of the need to
create maintainable software. Other dynamic languages like JavaScript\(^1\), Python\(^2\), Ruby\(^3\), PHP\(^4\), and Lua\(^5\) have followed suit.

Many contract systems\([35, 13, 23, 10, 37, 48, 17, 2]\) are language-embedded: contracts are first-class values constructed through some library API. This approach is advantageous because it does not tie the contract system to a particular implementation, it neither requires users to learn a separate contract language nor do implementors have to develop specialized contract tools. As the contract system can be distributed as a library, it is easily extensible.

But there are also disadvantages because the contract execution may get entangled with the application code. For example, every contract system supports “flat” contracts which assert that a predicate holds for a value. In most language-embedded systems, the predicate is just a host-language function returning a boolean value. Unlike a real predicate, such a function may have side effects that change the behavior of the application code.

Contributions

We present the design and implementation of TreatJS, a language embedded, higher-order contract system for JavaScript\([22]\) which enforces contracts by run-time monitoring. TreatJS supports most features of existing systems and a range of novel features that have not been implemented in this combination before. No source code transformation or change in the JavaScript run-time system is required. In particular, TreatJS is the first contract system for JavaScript that supports the standard features of contemporary contract systems (embedded contract language, JavaScript in flat contracts, contracts as projections, full interposition using JavaScript proxies\([49]\)) in combination with the following three novel points.

1. Noninterference. Contracts are guaranteed not to exert side effects on a contract abiding program execution. A predicate is an arbitrary JavaScript function, which can access the state of the application program but which cannot change it. An exception thrown by a predicate is not visible to the application program. Our guarantees are explained in detail in Section 4.3.

2. Dynamic contract construction. Contracts can be constructed and composed at run time using contract abstractions without compromising noninterference. A contract abstraction may contain arbitrary JavaScript code; it may read from global state and it may maintain encapsulated local state. The latter feature can be used to construct recursive contracts lazily or to remember values from the prestate of a function for checking the postcondition.

3. New contract operators. Beyond the standard contract constructors (flat, function, pairs), TreatJS supports object, intersection, and union contracts. Furthermore, contracts can be combined arbitrarily with the boolean connectives: conjunction, disjunction, and negation.

The discussion of related work in Section 6 contains a detailed comparison with other systems. The implementation of the system is available on the Web\(^6\).

Overview

The rest of this paper is organized as follows: Section 2 introduces TreatJS from a programmer’s point of view. Section 3 specifies contract monitoring and Section 4 explains the principles underlying the implementation. Section 5 reports our experiences from applying TreatJS to a range of benchmark programs. Section 6 discusses related work and Section 7 concludes.

Further technical details, examples, and a formalization of contracts and contract monitoring are included in the appendix.

2 A TreatJS Primer

The design of TreatJS obeys the following rationales.

- **Simplicity and orthogonality.** A core API provides the essential features in isolation. While complex contracts may require using the core API, the majority of contracts can be stated in terms of a convenience API that TreatJS provides on top of the core.
- **Non-interference.** Contract checking does not interfere with contract abiding executions of the host program.
- **Composability.** Contracts can be composed arbitrarily.

A series of examples explains how contracts are written and how contract monitoring works. The contract API includes constructors that build contracts from other contracts and auxiliary data as well as an assert function that attaches a contract to a JavaScript value.

Our discussion focuses on general design issues for contracts and avoids JavaScript specifics where possible. Contracts.js [19] provides contracts tailored to the idiosyncrasies of JavaScript’s object system—these may be added to TreatJS easily.

2.1 Base Contracts

The base contract (aka flat contract) is the fundamental building block for all other contracts. It is defined by a predicate and asserting it to a value immediately sets it in action. We discuss it for completeness—all contract libraries that we know of provide this functionality, but they do not guarantee noninterference like TreatJS does.

In JavaScript, any function can be used as a predicate, because any return value can be converted to boolean. JavaScript programmers speak of truthy or falsy about values that convert to true or false. Thus, a predicate holds for a value if applying the function evaluates to a truthy value.

For example, the function typeofNumber checks its argument to be a number. We apply the appropriate contract constructor to create a base contract from it.

```
function typeofNumber (arg) {
  return (typeof arg) === 'number';
}

var typeNumber = Contract.Base(typeofNumber);
```

Contract is the object that encapsulates the TreatJS implementation. Its assert function attaches a contract to a value. Attaching a base contract causes the predicate to be checked immediately. If the predicate holds, assert returns the original value. Otherwise, assert signals a contract violation blaming the subject.

In the following example, the first assert returns 1 whereas the second assert fails.
Listing 1 Some utility contracts.

Listing 1 defines a number of base contracts for later use. Analogous to typeNumber, the contracts typeBoolean and typeString check the type of their argument. Contract isArray checks if the argument is an array. Its correct implementation requires the With operator, which will be explained in Section 2.4.

2.2 Higher-Order Contracts

The example contracts in Subsection 2.1 are geared towards values of primitive type, but a base contract may also specify properties of functions and other objects. However, base contracts are not sufficiently expressive to state interesting properties of objects and functions. For example, a contract should be able to express that a function maps a number to a boolean or that a certain field access on an object always returns a number.

2.2.1 Function Contracts

Following Findler and Felleisen [25], a function contract is built from zero or more contracts for the arguments and one contract for the result of the function. Asserting the function contract amounts to asserting the argument contracts to the arguments of each call of the function and to asserting the result contract to the return value of each call. Asserting a function contract to a value immediately signals a contract violation if the value is not a function. Nevertheless, we call a function contract delayed, because asserting it to a function does not immediately signal a contract violation.

As a running example, we develop several contracts for the function cmpUnchecked, which compares two values and returns a boolean.

function cmpUnchecked(x, y) {
  return (x > y);
}

Our first contract restricts the arguments to numbers and asserts that the result of the comparison is a boolean.

var cmp = Contract.assert(cmpUnchecked,
  Contract.AFunction([typeNumber,typeNumber],typeBoolean));
AFunction is the convenience constructor for a function contract. Its first argument is an array with $n$ contracts for the first $n$ function arguments and the last argument is the contract for the result. This contract constructor is sufficient for most functions that take a fixed number of arguments.

The contracted function accepts arguments that satisfies contract typeNumber and promises to return a value that satisfies typeBoolean. If there is call with an argument that violates its contract, then the function contract raises an exception blaming the context, which is the caller of the function that provides the wrong kind of argument. If the argument is ok but the result fails, then blame is assigned to the subject (i.e., the function itself). Here are some examples that exercise cmp.

```javascript
22 cmp(1,2); // accepted
23 cmp('a','b'); // violation, blame the context
```

To obtain a subject violation we use a broken version of cmpUnchecked that sometimes returns a string.

```javascript
24 var cmpBroken = function(x, y) {
   return (x>0 & y>0) ? (x > y) : 'error';
};
25 var faultyCmp = Contract.assert(cmpBroken,
   Contract.AFunction([typeNumber,typeNumber],typeBoolean));
26 faultyCmp(0,1); // violation, blame the subject
```

Higher-order contracts may be defined in the usual way and their blame reporting in TreatJS follows Findler and Felleisen [25]. For example, a function sort, which takes an array and a numeric comparison function as arguments and which returns an array, may be specified by the following contract, which demonstrates nesting of function contracts.

```javascript
27 var sortNumbers = Contract.AFunction([isArray, cmp], isArray);
```

Higher-order contracts open up new ways for a function not to fulfill its contract. For example, sort may violate the contract by calling its comparison function (contracted with cmp) with non-numeric arguments. Generally, the context is responsible to pass an argument that satisfies its specification to the function and to use the function’s result according to its specification. Likewise, the function is responsible for the use of its arguments and in case the arguments meet their specification to return a value that conforms to its specification.

In general, a JavaScript function has no fixed arity and arguments are passed to the function in a special array-like object, the arguments object. Thus, the core contract Function takes two arguments. The first argument is an object contract (cf. Subsubsection 2.2.2) that maps an argument index (starting from zero) to a contract. The second argument is the contract for the function’s return value. Thus, AFunction creates an object contract from the array in its first argument and passes it to Function.

Using the core Function contract is a bit tricky because it exposes the unwary contract writer to some JavaScript internals. The contract Function(isArray, typeNumber) checks whether the arguments object is an array (which it is not), but it does not check the function’s arguments. As a useful application of this feature, the following contract twoArgs checks that a function is called with exactly two arguments.

```javascript
31 var lengthTwo = Contract.Base(function (args) {
   return (args.length == 2);
});
32 var Any = Contract.Base (function() { return true; });
```
2.2.2 Object Contracts

Apart from base contracts that are checked immediately and delayed contracts for functions, TreatJS provides contracts for objects. An object contract is defined by a mapping from property names to contracts. Asserting an object contract to a value immediately signals a violation if the value is not an object. The contracts in the mapping have no immediate effect. However, when reading a property of the contracted object, the contract associated with this property is asserted to the property value. Similarly, when writing a property, the new value is checked against the contract. This way, each value read from a property and each value that is newly written into the property is guaranteed to satisfy the property’s contract. Reads and writes to properties not listed in an object contract are not checked.

The following object contract indicates that the `length` property of an object is a number.

```javascript
var arraySpec = Contract.AObject({length:typeNumber});
```

Any array object would satisfy this contract. Each access to the `length` property of the contracted array would be checked to satisfy `typeNumber`.

Blame assignment for property reads and writes is inspired by Reynolds [45] interface for a reference cell: each property is represented as a pair of a getter and a setter function. Both, getter and setter apply the same contract, but they generate different blame. If the contract fails in the getter, then the `subject` (i.e., the object) is blamed. If the contract fails in the setter, then the `context` (i.e., the assignment) is blamed. The following example illustrates this behavior.

```javascript
var faultyObj = Contract.assert({length:'1'}, arraySpec);
faultyObj.length; // violation, blame the subject
faultyObj.length='1'; // violation, blame the context
```

An object contract may also serve as the domain portion in a function contract. It gives rise to yet another equivalent way of writing the contract from Line 21.

```javascript
Contract.Function(
  Contract.AObject([typeNumber, typeNumber]), typeBoolean);
```

Functions may also take an intersection (cf. Section 2.3) of a function contract and an object contract to address properties of functions and `this`. There is also a special `Method` contract that includes a contract specification for `this`.

2.3 Combination of Contracts

Beyond base, function, and object contracts, TreatJS provides the intersection and union of contracts as well as the standard boolean operators on contracts: conjunction (`And`), disjunction (`Or`), and negation (`Not`). The result of an operator on contracts is again a contract that may be further composed.

For space reasons, we only discuss intersection and union contracts, which are inspired by the corresponding operators in type theory. If a value has two types, then we can assign it an intersection type [14]. It is well known that intersection types are useful to model overloading and multiple inheritance.
As an example, we revisit `cmpUnchecked`, which we contracted with `cmpNumbers` in Section 2.2.1 to ensure that its arguments are numbers. As the comparison operators are overloaded to work for strings, too, the following contract is appropriate.

\[
\text{Contract.Intersection}
\]

\[
\text{Contract.AFunction([typeNumber, typeNumber], typeBoolean),}
\]

\[
\text{Contract.AFunction([typeString, typeString], typeBoolean));}
\]

This contract blames the context if the contracted function is applied to arguments that fail both domain contracts, that is, `[typeNumber, typeNumber]` and `[typeString, typeString]`. The subject is blamed if a function call does not fulfill the range contract that corresponds to a satisfied domain contract.

This interpretation coincides nicely with the meaning of an intersection type. The caller may apply the function to arguments both satisfying either `typeNumber` or `typeString`. In general, the argument has to satisfy the union of `typeNumber` and `typeString`. For disjoint arguments the intersection contract behaves identically to the disjunction contract.

As in type theory, the union contract is the dual of an intersection contract. Exploiting the well-known type equivalence \((A \to C) \land (B \to C) = (A \lor B) \to C\) [5], we may rephrase the above contract with a union contract, which accepts either a pair of numbers or a pair of strings as function arguments:

\[
\text{Contract.Function/}
\]

\[
\text{Contract.Union/}
\]

\[
\text{Contract.AObject([typeNumber, typeNumber]),}
\]

\[
\text{Contract.AObject([typeString, typeString]), typeBoolean);}
\]

Next, we consider the union of two function contracts.

\[
\text{var uf = Contract.Union/}
\]

\[
\text{Contract.AFunction([typeNumber,typeNumber], typeBoolean),}
\]

\[
\text{Contract.AFunction([typeString,typeString], typeBoolean));}
\]

Asserting this contract severely restricts the domain of a function. An argument is only acceptable if it is acceptable for all function contracts in the union. Thus, the context is blamed if it provides an argument that does not fulfill both constituent contracts. For example, `uf` requires an argument that is both a number and a string. As there is no such argument, any caller will be blamed.

For a sensible application of a union of function contracts, the domains should overlap:

\[
\text{Contract.Union(}
\]

\[
\text{Contract.AFunction([typeNumber, typeNumber], typeBoolean),}
\]

\[
\text{Contract.AFunction([typeNumber, typeNumber], typeString));}
\]

This contract is satisfied by a function that either always returns a boolean value or by one that always returns a string value. It is not satisfied by a function that alternates between both return types between calls. A misbehaving function is blamed on the first alternation.

### 2.4 Sandboxing Contracts

All contracts of `TreatJS` guarantee noninterference: Program execution is not influenced by the evaluation of a terminating predicate inside a base contract. That is, a program with
contracts is guaranteed to read the same values and write to the same objects as without contracts. Furthermore, it either signals a contract violation or returns a results that behaves the same as without contracts.

To achieve this behavior, predicates must not write to data structures visible outside of the predicate. For this reason, predicate evaluation takes place in a sandbox that hides all external bindings and places a write protection on objects passed as parameters.

To illustrate, we recap the `typeNumber` contract from Line 4. Without the sandbox we could abstract the target type of `typeNumber` with a function and build base contracts by applying the function to different type names as in the following attempt:

```javascript
function badTypeOf(type) {
  return Contract.Base(function(arg) {
    return (typeof arg) === type;
  });
}
var typeNumberBad = badTypeOf('number');
var typeStringBad = badTypeOf('string');
```

However, this code fragment does not work as expected. The implementation method for our sandbox reopens the closure of the anonymous function in line 57 and removes the binding for `type` from the contract’s predicate. Both `typeNumberBad` and `typeStringBad` would be stopped by the sandbox because they try to access the (apparently) global variable `type`. This step is required to guarantee noninterference, because the syntax of predicates is not restricted in their expressiveness and programmers may do arbitrary things, including communicating via global variables or modifying data outside the predicate’s scope.

In general, read-only access to data (functions and objects) is safe and many useful contracts (e.g., the `isArray` contract from Line 10 references the global variable `Array`) require access to global variables, so a sandbox should permit regulated access.

Without giving specific permission, the sandbox rejects any access to the `Array` object and signals a sandbox violation. To grant read permission, a new contract operator `With` is needed that makes an external reference available inside the sandbox. The `With` operator takes a binding object that maps identifiers to values and a contract. Evaluating the resulting contract installs the binding in the sandbox environment and then evaluates the constituent contract with this binding in place. Each value passed into the sandbox (as an argument or as a binding) is wrapped in an identity preserving membrane [49] to ensure read-only access to the entire object structure.

The `With` constructor is one approach to build parameterized contracts by providing a form of dynamic binding.

```javascript
var typeOf = Contract.Base(function(arg) {
  return (typeof arg) === type;
});
var typeNumber = Contract.With({type: 'number'}, typeOf);
var typeString = Contract.With({type: 'string'}, typeOf);
```

For aficionados of lexical scope, contract constructors, explained in the next subsection, are another means for implementing parameterized contracts.

### 2.5 Contract Constructors

While sandboxing guarantees noninterference, it prohibits the formation of some useful contracts. For example, the range portion of a function contract may depend on the
arguments or a contract may enforce a temporal property by remembering previous function calls or previously accessed properties. Implementing such a facility requires that predicates should be able to store data without affecting normal program execution.

TreatJS provides a contract constructor Constructor for building a parameterized contract. The constructor takes a function that maps the parameters to a contract. This function is evaluated in a sandbox, like a predicate. Unlike a predicate, the function may contain contract definitions and must return a contract. Each contract defined inside the sandbox is associated with the same sandbox environment and shares the local variables and the parameters visible in the function’s scope. No further sandboxing is needed for the predicates / base contracts defined inside the sandbox. The returned contract has no ties to the outside world and thus the included predicates will not be evaluated in the sandbox again. If such a predicate is called, the encapsulated sandbox environment can be used to store data for later use and without affecting normal program execution.

In the next example, a contract constructor builds a base contract from the name of a type. The constructor provides a lexically scoped alternative to the approach in Line 63.

```javascript
var Type = Contract.Constructor(function(type) {
  return Contract.Base(function(arg) {
    return (typeof arg) === type;
  });
});
```

To obtain the actual contract we apply the constructor to parameters with the method `Contract.construct` or by using the `construct` method of the constructor.

```javascript
var typeNumber = Type.construct('number');
var typeString = Type.construct('string');
```

Let’s consider yet another contract for a compare function. For this contract, we only want the contract of the comparison to state that the two arguments have the same type.

```javascript
Contract.Constructor(function() {
  var type;
  var getType = Contract.Base(function (arg) {
    return type = (typeof arg);
  });
  var checkType = Contract.Base(function (arg) {
    return type === (typeof arg);
  });
  var typeBoolean = Contract.Base(function (arg) {
    return (typeof arg) === 'boolean';
  });
  return Contract.AFunction([getType, checkType], typeBoolean);
});
```

This code fragment defines a constructor with zero parameters (viz. the empty parameter list in Line 75). As there are no parameters, this example only uses the constructor to install a shared scope for several contracts. The contract `getType` saves the type of the first argument. The comparison function has to satisfy a function contract which compares the type of the second arguments with the saved type.
2.6 Dependent Contracts

A dependent contract is a contract on functions where the range portion depends on the function argument. The contract for the function’s range can be created with a contract constructor. This constructor is invoked with the caller’s argument. Additionally, it is possible to import pre-state values in the scope of the constructor so that the returned contract may refer to those values.

*TreatJS*’s dependent contract operation only builds a range contract in this way; it does not check the domain as checking the domain may be achieved by conjunction with another function contract. By either pre- or postcomposing the other contract, the programmer may choose between picky and lax semantics for dependent contracts (cf. [30]).

For example, a dependent contract *PreserveLength* may specify that an array processing function like *sort* (Line 30) preserves the length of its input. The constructor receives the arguments (input array and comparison function) of a function call and returns a contract for the range that checks that the length of the input array is equal to the length of the result.

```javascript
var PreserveLength = Contract.Dependent(
  Contract.Constructor(function(input, cmp) {
    return Contract.Base(function(result) {
      return (input.length === result.length);
    });
  }));
```

3 Contract Monitoring

This section explains how contract monitoring works and how the outcome of a contract assertion is determined by the outcome of its constituents. For space reasons we focus on the standard contract types (base, function, and object contracts) with intersection and union; we describe the boolean operators in the supplemental material.

3.1 Contracts and Normalization

A contract is either an immediate contract, a delayed contract, an intersection between an immediate and a delayed contract, or a union of contracts. Immediate contracts may be checked right away when asserted to a value whereas delayed contracts need to be checked later on. Only a base contract is immediate.

A delayed contract is a function contract, a dependent contract, an object contract, or an intersection of delayed contracts. Intersections are included because all parts of an intersection must be checked on each use of the contracted object: a call to a function or an access to an object property.

The presence of operators like intersection and union has severe implications. In particular, a failing base contract must not signal a violation immediately because it may be enclosed in an intersection. Reporting the violation must be deferred until the enclosing operator is sure to fail.

To achieve the correct behavior for reporting violations, monitoring normalizes contracts before it starts contract enforcement. Normalization separates the immediate parts of a contract from its delayed parts so that each immediate contract can be evaluated directly,
whereas the remaining delayed contracts wrap the subject of the contract in a proxy that asserts the contract when the subject is used.

To expose the immediate contracts, normalization first pulls unions out of intersections by applying the distributive law suitably. The result is a union of intersections where the operands of each intersection are either immediate contracts or function contracts. At this point, monitoring can check all immediate contracts and set up proxies for the remaining delayed contracts. It remains to define the structure needed to implement reporting of violations (i.e., blame) that is able to deal with arbitrary combinations of contracts.

3.2 Callbacks

To assert a contract correctly, its evaluation must connect each contract with the enclosing operations and it must keep track of the evaluation state of these operations. In general, the signaling of a violation depends on a combination of failures in different contracts.

This connection is modeled by so-called callbacks. They are tied to a particular contract assertion and link each contract to its next enclosing operation or, at the top-level, its assertion. A callback linked to a source-level assertion is called root callback. Each callback implements a constraint that specifies the outcome of a contract assertion in terms of its constituents.

A callback is implemented as a method that accepts the result of a contract assertion. The method updates a shared property, it evaluates the constraint, and passes the result to the enclosing callback.

Each callback is related to one specific contract occurrence in the program; there is at least one callback for each contract occurrence and there may be multiple callbacks for a delayed contract (e.g., a function contract). The callback is associated with a record that defines the blame assignment for the contract occurrence. This record contains two fields, subject and context. The intuitive meaning of the fields is as follows. If the subject field is false, then the contract fails blaming the subject (i.e., the value to which the contract is asserted). If the context field is false, then the contract fails blaming the context (i.e., the user of the value to which the contract is asserted).

3.3 Blame Calculation

The fields in the record range over $\mathbb{B}_4$, the lattice underlying Belnap’s four-valued logic [6], which is intended to deal with incomplete or inconsistent information. The set $\mathbb{B}_4 = \{\bot, f, t, \top\}$ of truth values forms a lattice modeling accumulated knowledge about the truth of a proposition. Thus, a truth value may be considered as the set of classical truth values $\{true, false\}$ that have been observed so far for a proposition. For instance, contracts are valued as $\bot$ before they are evaluated and $\top$ signals potentially conflicting outcomes of repeated checking of the same contract.

As soon as a base contract’s predicate returns, the contract’s callback is applied to its outcome. A function translates the outcome to a truth value according to JavaScript’s idea of truthy and falsy, where false, undefined, null, NaN, and “” is interpreted as false. Exceptions thrown during evaluation of a base contract are captured and count as $\top$.

A new contract assertion signals a violation if a root callback maps any field to $f$ or $\top$. Evaluation continues if only internal fields have been set to $f$ or $\top$.

3.4 Contract Assertion

Contract monitoring starts when calling the assert function with a value and a contract.
The top-level assertion first creates a new root callback that may signal a contract violation later on and an empty sandbox object that serves as the context for the internal contract monitoring. The sandbox object carries all external values visible to the contract.

Asserting a base contract to a value wraps the value to avoid interference and applies the predicate to the wrapped value. Finally, it applies the current callback function to the predicate's outcome.

Asserting a delayed contract to an object results in a proxy object that contains the current sandbox object, the associated callback, and the contract itself. It is an error to assert a delayed contract to a primitive value.

Asserting a union contract first creates a new callback that combines the outcomes of the subcontracts according to the blame propagation rules for the union. Then it asserts the first subcontract (with a reference to one input of the new callback) to the value before it asserts the second subcontract (with a reference to the other input) to the resulting value.

Asserting a With contract first wraps the values defined in the binding object and builds a new sandbox object by merging the resulting values and the current sandbox object. Then it asserts its subcontract.

3.5 Application, Read, and Assignment

Function application, property read, and property assignment distinguish two cases: either the operation applies directly to a non-proxy object or it applies to a proxy. If the target of the operation is not a proxy object, then the standard operation is applied.

If the target object is a proxy with a delayed contract, then the contract is checked when the object is used as follows.

A function application on a contracted function first creates a fresh callback that combines the outcomes of the argument and range contract according to the propagation rules for functions. Then it asserts the domain contract to the argument object with reference to the domain input of the new callback before it applies the function to the result. After completion, the range contract is applied to the function’s result with reference to the range input of the callback.

A function application on a function contracted with a dependent contract first applies the contract constructor to the argument and saves the resulting range contract. Next, it applies the function to the argument and asserts the computed range contract to the result.

A property access on a contracted object has two cases depending on the presence of a contract for the accessed property. If a contract exists, then the contract is asserted to the value after reading it from the target object and before writing it to the target object. Otherwise, the operation applies directly to the target object.

Property write creates a fresh callback that inverts the responsibility of the contract assertion (the context has to assign a value according to the contract).

An operation on a proxy with an intersection contract asserts the first subcontract to the value before it asserts the second subcontract to the resulting value. Both assertions are connected to one input channel of a new callback that combines their outcomes according to the rules for intersection.

All contract assertions forward the sandbox object in the proxy to the subsequent contract assertion.
3.6 Sandbox Encapsulation

The sandbox ensures noninterference with the actual program code by stopping evaluation of the predicate if it attempts to modify data that is visible outside the contract.\footnote{The sandbox cannot ensure termination of the predicate, of course.}

To ensure noninterference, the subject of a base contract, the argument of a dependent contract as well as the value passed by a contract constructor are all wrapped in a membrane to ensure that the contract’s code cannot modify them in any way.

To wrap a non-proxy object, the object is packaged in a fresh proxy along with the current sandbox object. This packaging ensures that further access to the wrapped object uses the current sandbox object. If the object points to a contracted object, the wrap operation continues with the target object, before adding all contracts from the contracted object. A primitive value is not wrapped.

A property read on a sandboxed object forwards the operation to the target and wraps the resulting behavior. An assignment to a sandboxed object is not allowed, thus it signals a sandbox violation.

The application of a sandboxed function recompiles the function by adding the given sandbox object to the head of the scope chain. Finally, it calls the function. The function’s argument and its result are known to be wrapped in this case.

3.7 Contract Satisfaction

The blame assignment for a function contract is calculated from the blame assignment for the argument and result contracts, which are available through the records $\iota_d$ and $\iota_r$. A function does not fulfill a contract if it does not fulfill its obligations towards its argument $\iota_d\text{.context}$ or if the argument fulfills its contract, but the result does not fulfills its contract $\iota_d\text{.subject} \Rightarrow \iota_r\text{.subject}$. The first part arises for higher-order functions, which may pass illegal arguments to their function-arguments. The second part corresponds to partial correctness of the function with respect to its contract.

A function’s context (caller) fulfills the contract if it passes an argument that fulfills its
contract \( \tau_s \cdot \text{subject} \) and it uses the function result according to its contract \( \tau_r \cdot \text{context} \). The second part becomes non-trivial with functions that return functions.

An object (subject) does not fulfill an object contract if a property access returns a value that does not fulfill the contract. An object’s context (caller) does not fulfill the contract if it assigns an illegal value to a contracted property or it does not uses the objects return according to its contract.

The outcome of read access on a contracted property \( \tau_c \cdot \text{subject} \) is directly related to the parent callback and does not need a special constraint. A write to a property guarded with contract \( C \) generates blame like a call to a function with contract \( C \rightarrow \text{Any} \). (\text{Any} accepts any value.)

The blame assignment for an intersection contract is defined from its constituents at \( \tau_r \) and \( \tau_l \). A subject fulfills an intersection contract if it fulfills both constituent contracts: \( \tau_r \cdot \text{subject} \land \tau_l \cdot \text{subject} \). A context, however, only needs to fulfill one of the constituent contracts: \( \tau_r \cdot \text{context} \lor \tau_l \cdot \text{context} \).

Dually to the intersection rule, the blame assignment for a union contract is determined from its constituents at \( \tau_l \) and \( \tau_r \). A subject fulfills a union contract if it fulfills one of the constituent contracts: \( \tau_l \cdot \text{subject} \lor \tau_r \cdot \text{subject} \). A context, however, needs to fulfill both constituent contracts: \( \tau_l \cdot \text{context} \land \tau_r \cdot \text{context} \), because it does not known which contract is fulfilled by the subject.

Figure 1 illustrates the working of callbacks. After applying \text{addOne} to ’1’, the first function contract \((\text{Num} \rightarrow \text{Num})\) would fail blaming the context, whereas the second contract \((\text{Str} \rightarrow \text{Str})\) succeeds. Because the context of an intersection may choose which side to fulfill, the intersection is satisfied.

However, the second call which applies \text{addOne} to 1 raises an exception. The first function contract fails, blaming the subject, whereas the second contract fails, blaming the context. Because the subject of an intersection has to fulfill both contracts, the intersection fails, blaming the subject.

## 4 Implementation

The implementation is based on the JavaScript Proxy API [49, 50], a part of the ECMAScript 6 draft standard. This API is implemented in Firefox since version 18.0 and in Chrome V8 since version 3.5. Our development is based on the SpiderMonkey JavaScript engine.

### 4.1 Delayed Contracts

Delayed contracts are implemented using JavaScript Proxies [49, 50], which guarantees full interposition by intercepting all operations. The assertion of a delayed contract wraps the subject of the contract in a proxy. The handler for the proxy contains the contract and implements traps to mediate the use of the subject and to assert the contract. No source code transformation or change in the JavaScript run-time system is required.

### 4.2 Sandboxing

Our technique to implement sandboxing relies on all the evil and bad parts of JavaScript: the \text{eval} function and the \text{with} statement. The basic idea is as follows. The standard implementation of the \text{toString} method of a user-defined JavaScript function returns a string that contains the source code of that function. When \text{TreatJS} puts a function (e.g., a predicate) in a sandbox, it first disassembles it by calling its \text{toString} method. Applying \text{eval}
to the resulting string creates a fresh variant of that function, but it dynamically rebinds the free variables of the function to whatever is currently in the scope at the call site of eval.

JavaScript's `with (obj){ ... body ... }` statement modifies the current environment by placing `obj` on top of the scope chain while executing `body`. With this construction, which is somewhat related to dynamic binding [32], any property defined in `obj` shadows the corresponding binding deeper down in the scope chain. Thus, we can add and shadow bindings, but we cannot remove them. Or can we?

It turns out that we can also abuse `with` to remove bindings! The trick is to wrap the new bindings in a proxy object, use `with` to put it on top of the scope chain, and to trap the binding object's `hasOwnProperty` method. When JavaScript traverses the scope chain to resolve a variable reference `x`, it calls `hasOwnProperty(x)` on the objects of the scope chain starting from the top. Inside the `with` statement, this traversal first checks the proxied binding object. If its `hasOwnProperty` method always returns true, then the traversal stops here and the JavaScript engine sends all read and write operations for free variables to the proxied binding object. This way, we obtain full interposition and the handler of the proxied binding object has complete control over the free variables in `body`.

The `With` contract is `TreatJS`'s interface to populate this binding object. The operators for contract abstraction and dependent contracts all take care to stitch the code fragments together in the correct scope. To avoid the frequent decompilation and `eval` of the same code, our implementation caches the compiled code where applicable.

No value is passed inside the sandbox without proper protection. Our protection mechanism is inspired by Revocable Membranes [49, 46]. A membrane serves as a regulated communication channel between two worlds, in this case between an object/ a function and the rest of a program. A membrane is essentially a proxy that guards all read operations and—in our case—stops all writes. If the result of a read operation is an object, then it is recursively wrapped in a membrane before it is returned. Access to a property that is bound to a getter function needs to decompile the getter before its execution. Care is taken to preserve object identities when creating new wrappers (our membrane is `identity preserving`).

We employ membranes to keep the sandbox apart from normal program execution thus guaranteeing noninterference. In particular, we encapsulate objects passed through the membrane, we enforce write protection, and we withhold external bindings from a function.

### 4.3 Noninterference

The ideal contract system should not interfere with the execution of application code. That is, as long as the application code does not violate any contract, the application should run as if no contracts were present. Borrowing terminology from security, this property is called noninterference (NI) [28]: with the assumption that contract code runs at a higher level of security than application code, the low security application code should not be able to observe the results of the high-level contract computation.

Looking closer, we need to distinguish internal and external sources of interference. Internal sources of interference arise from executing unrestricted JavaScript code in the predicate of a base contract. This code may try to write to an object that is visible to the application, it may throw an exception, or it may not terminate. Our implementation restricts all write operations to local objects using sandboxing. It captures all exceptions and turns them into an appropriate contract outcome. A timeout could be used to transform a contract that may not terminate into an exception, alas, such a timeout cannot be implemented in
External interference arises from the interaction of the contract system with the language. Two such issues arise in a JavaScript contract system, exceptions and object equality.

Exceptions arise when a contract failure is encoded by a contract exception, as it is done in Eiffel, Racket, and contracts.js. If an application program catches exceptions, then it may become aware of the presence of the contract system by observing an exception caused by a contract violation. Our implementation avoids this problem by reporting the violation and then using a JavaScript API method to quit JavaScript execution\footnote{The JavaScript \texttt{timeout} function only schedules a function to run when the currently running JavaScript code—presumably some event handler—stops. It cannot interrupt a running function.}.

Object equality becomes an issue because function contracts as well as object contracts are implemented by some kind of wrapper. The problem arises if a wrapper is different (i.e., not pointer-equal) from the wrapped object so that an equality test between wrapper and wrapped object or between different wrappers for the same object (read: tests between object and contracted object or between object with contract A and object with contract B) in the application program returns false instead of true.

Our implementation uses JavaScript proxies to implement wrappers. Unfortunately, JavaScript proxies are always different from their wrapped objects and the only safe way to change that is by modifying the proxy implementation in the JavaScript VM. See our companion paper \cite{36} for more discussion. There are proposals based on preprocessing all uses of equality to proxy-dereferencing equality, for example using SweetJS \cite{20}, but they do not work in combination with \texttt{eval} and hence do not provide full interposition.

\section{Evaluation}

This section reports on our experience with applying contracts to select programs. We focus on the influence of contract assertion and sandboxing on the execution time.

All benchmarks were run on a machine with two AMD Opteron Processor with 2.20 GHz and 64 GB memory. All example runs and timings reported in this paper were obtained with the SpiderMonkey JavaScript engine.

\subsection{Benchmark Programs}

To evaluate our implementation, we applied it to JavaScript benchmark programs from the Google Octane 2.0 Benchmark Suite\footnote{https://developers.google.com/octane/}. Octane 2.0 consists of 17 programs that range from performance tests to real-world web applications (Figure 2), from an OS kernel simulation to a portable PDF viewer. Each program focuses on a special purpose, for example, function and method calls, arithmetic and bit operations, array manipulation, JavaScript parsing and compilation, etc.

Octane reports its result in terms of a score. The Octane FAQ\footnote{https://developers.google.com/octane/faq} explains the score as follows: "In a nutshell: bigger is better. Octane measures the time a test takes to complete and then assigns a score that is inversely proportional to the run time." The constants in this computation are chosen so that the current overall score (i.e., the geometric mean of the individual scores) matches the overall score from earlier releases of Octane and new
benchmarks are integrated by choosing the constants so that the geometric mean remains the same. The rationale is to maintain comparability.

5.2 Methodology

To evaluate our implementation, we wrote a source-to-source compiler that first modifies the benchmark code by wrapping each function expression\footnote{Function expressions are all expressions of the form \texttt{function(\ldots)\{\ldots\}.}} in an additional function. In a first run, this additional function wraps its target function in a proxy that, for each call to the function, records the data types of the arguments and of the function’s return value. This recording distinguishes the basic JavaScript data types \texttt{boolean}, \texttt{null}, \texttt{undefined}, \texttt{number}, \texttt{string}, \texttt{function}, and \texttt{object}. Afterwards, the wrapper function is used to assert an appropriate function contract to each function expression. These function contracts are built from the types recorded during the first phase. If more than one type is recorded at a given program point, then the disjunction of the individual type contracts is generated.

All run-time measurements were taken from a deterministic run, which requires a pre-defined number of iterations, and by using a warm-up run.

5.3 Results

Figure 2 contains the scores of all benchmark programs in different configurations, which are explained in the figure’s caption. As expected, all scores decrease when adding contracts. The impact of a contract depends on the frequency of its application. A contract on a heavily used function (e.g., in \texttt{Richards}, \texttt{DeltaBlue}, or \texttt{Splay}) causes a significantly higher decrease of the score. These examples show that the run-time impact of contract assertion depends on the program and on the particular value that is monitored. While some programs like \texttt{Richards}, \texttt{DeltaBlue}, \texttt{RayTrace}, and \texttt{Splay} are heavily affected, others are almost unaffected: \texttt{Crypto}, \texttt{NavierStokes}, and \texttt{Mandreel}, for instance.

In several cases the execution with contracts (or with a particular feature) is faster than without. All such fluctuations in the score values are smaller than the standard deviation over several runs of the particular benchmark.

For better understanding, Figure 3 lists some numbers of internal counters. The numbers indicate that the heavily affected benchmarks (\texttt{Richards}, \texttt{DeltaBlue}, \texttt{RayTrace}, \texttt{Splay}) contain a very large number of internal contract assertions. Other benchmarks are either not affected (\texttt{RegExp}, \texttt{zlib}) or only slightly affected (\texttt{Crypto}, \texttt{pdf.js}, \texttt{Mandreel}) by contracts.

For example, the \texttt{Richards} benchmark performs 24 top-level contract assertions (these are all calls to \texttt{Contract.assert}), 1.6 billion internal contract assertions (including top-level assertions, \texttt{delayed} contract checking, and predicate evaluation), and 936 million predicate executions. The sandbox wraps about 4.7 billion elements, but performs only 4 decompile operations. Finally, contract checking performs 3.4 billion callback update operations.

Because of the fluctuation in slightly affected benchmark programs the following discussion focuses on benchmarks that were heavily impacted. Thus, we ignore the benchmark programs \texttt{Crypto}, \texttt{RegExp}, \texttt{pdf.js}, \texttt{Mandreel}, \texttt{zlib}.

In a first experiment, we turn off predicate execution and return \texttt{true} instead of the predicate’s result. This splits the performance impact into the impact caused by the contract system (proxies, callbacks, and sandboxing) and the impact caused by evaluating predicates. From the score values we find that the execution of the programmer provided predicates

Figure 2: Scores for the Google Octane 2.0 Benchmark Suite (bigger is better). Column **F** (Full) contains the scores for running with sandboxed contract assertion. Column **S** (System only) contains the score values for running TreatJS without predicate evaluation (all predicates are set to true) but with all internal components (callback, decompile, membrane). Column **w/o C** (without callback) shows the scores from a full run (with predicates) but without callback updates. Column **w/o D** (without decompile) shows the scores without recompiling functions. Column **w/o M** (without membrane) lists the scores with contract assertion but without sandboxing (and thus without decompile). Column **w/o P** (without predicate) shows the score values of raw contract assertions without predicate evaluation and thus without sandboxing, decompile, and callback updates. The last column **B** (Baseline) gives the baseline scores without contract assertion.

causes a slowdown of 9.20% over all benchmarks (difference between **F** and **S**). The remaining slowdown is caused by the contract system itself. The subsequent detailed treatment of the score values splits the impact into its individual components.

Comparing columns **F** and **w/o C** shows that callback updates cause an overall slowdown of 4.25%. This point includes the recalculation of the callback constraints as explained in Section 3.7.

The numbers also show that decompiling functions has negligible impact on the execution time. Decompiling decreases the score by 6.29% over all benchmarks (compare columns **w/o C** and **w/o D**

$^{13}$ Function recompilation can be safely deactivated for the benchmarks without changing the outcome because our generated base contracts are guaranteed to be free of side effects.

Comparing the scores in columns **w/o D** and **w/o M** indicates that the membrane, as it is used by the sandbox, does not contribute significantly to the run-time overhead. It does not decrease the total scores.

Finally, after deactivating predicate execution, we see that pure predicate handling causes a slowdown of approximately 1.76% (this is the impact of the function calls). In contrast to column **S**, column **w/o P** shows the score values of the programs without sandboxing, without recompiling, and without callback updates, whereas in column **S** sandboxing, recompilation,

**Figure 3** Statistic from running the Google Octane 2.0 Benchmark Suite. Column A (Assert) shows the numbers of top-level contract assertions. Column I (Internal) contains the numbers of internal contract assertions whereby column P (Predicate) lists the number of predicate evaluations. Column M (Membrane) shows the numbers of wrap operation and column D (Decompile) show the numbers of decompile operations. The last column Callback gives the numbers of callback updates.

and callback updates remain active.

From the score values we find that the overall slowdown of sandboxed contract checking vs. a baseline without contracts amounts to a factor of 7136, approximately. The dramatic decrease of the score values in the heavily affected benchmarks is simply caused by the tremendous number of checks that arise during a run.

For example, in the Splay benchmark, the insert, find, and remove functions on trees are contracted. These functions are called every time a tree operation is performed. As the benchmark runs for 1400 iterations on trees with 8000 nodes, there is a considerable number of operations, each of which checks a contract. It should be recalled that every contract check performs at least two typeof checks.

Expressed in absolute time spans, contract checking causes a run time deterioration of 0.17ms for every single predicate check. For example, the contracted Richards requires 152480 seconds to complete and performs 935751200 predicate checks. Its baseline requires 8 seconds. Thus, contract checking requires 152472 seconds. That gives 0.16ms per predicate check.

Google claims that Octane “measure[s] the performance of JavaScript code found in large, real-world web applications, running on modern mobile and desktop browsers”\(^\text{14}\). For an academic, this is as realistic as it gets.

However, there are currently no large JavaScript application with contracts that we could use to benchmark, so we had to resort to automatic generation and insertion of contracts. These contracts may end up in artificial and unnatural places that would be avoided by an

\(^{14}\text{https://developers.google.com/octane/}^{14}$
efficiency conscious human developer. Thus, the numbers that we obtain give insight into the performance of our contract implementation, but they cannot be used to predict the performance impact of contracts on realistic programs with contracts inserted by human programmers. The scores of the real-world programs (pdf.js, Mandreel, Code Loading) among the benchmarks provide some initial evidence in this direction: their scores are much higher and they are only slightly effected by contract monitoring. But more experimentation is needed to draw a statistically valid conclusion.

6 Related Work

Contract Validation

Contracts may be validated statically or dynamically. Purely static frameworks (e.g. ESC/Java [26]) transform specifications and programs into verification conditions to be verified by a theorem prover. Others [52, 47] rely on symbolic execution to prove adherence to contracts. However, most frameworks perform run-time monitoring as proposed in Meyer’s work.

Higher-Order Contracts

Findler and Felleisen [25] first showed how to construct contracts and contract monitors for higher-order functional languages. Their work has attracted a plethora of follow-up works that range from semantic investigations [8, 24] over deliberations on blame assignment [16, 51] to extensions in various directions: contracts for polymorphic types [2, 7], for affine types [48], for behavioral and temporal conditions [18, 21], etc. While the cited semantic investigations consider noninterference, only Disney and coworkers [21] give noninterference a high priority and propose an implementation that enforces it. The other contract monitoring implementations that we are aware of, do not address noninterference or restrict their predicates.

Embedded Contract Language

Specification Languages like JML [39] state behavior in terms of a custom contract language or in terms of annotations in comments. An embedded contract language exploits the language itself to state contracts. Thus programmers need not learn a new language and the contract specification can use the full power of the language. Existing compilers and tools can be used without modifications.

Combinations of Contracts

Over time, a range of contract operators emanated, many of which are inspired by type operators. There are contract operators analogous to (dependent) function types [25], product types, sum types [35], as well as universal types [2]. Racket also implements restricted versions of conjunctions and disjunctions of contracts (see below). However, current systems do not support contracts analogous to union and intersection types nor do they support full boolean combination of contracts (negation is missing).

Dimoulas and Felleisen [15] propose a contract composition, which corresponds to a conjunction of contracts. But their operator is restricted to contracts of the same type. Before evaluating a conjunction it lifts the operator recursively to base contracts where it finally builds the conjunction of the predicate results.
Racket’s contract system [27, Chapter 7] supports boolean combinations of contracts. Conjunctions of contracts are decomposed and applied sequentially [47]. Disjunctions of flat contracts are transformed so that the first disjunct does not cause a blame immediately if its predicate fails. However, Racket places severe restrictions on using disjunction with higher-order contracts and restricts negation to base contracts. A disjunction must be resolved by first-order choice to at most one higher-order contract; otherwise it is rejected at run time.

Proxies

The JavaScript proxy API [49] enables a developer to enhance the functionality of objects easily. JavaScript proxies have been used for Disney’s JavaScript contract system, contracts.js [19], to enforce access permission contracts [37], as well as for other dynamic effects systems, meta-level extension, behavioral reflection, security, or concurrency control [42, 4, 9].

Sandboxing JavaScript

The most closely related work to our sandbox mechanism is the work of Arnaud et al. [3]. They provide features similar to our sandbox mechanism. Both approaches focus on access restriction and noninterference to guarantee side effect free assertions of contracts.

Our sandbox mechanism is inspired by the design of access control wrappers which is used for revocable references and membranes [49, 44]. In memory-safe languages, a function can only cause effects to objects outside itself if it holds a reference to the other object. The authority to affect the object can simply be removed if a membrane revokes the reference which detaches the proxy from its target.

Our sandbox works in a similar way and guarantees read-only access to target objects, but redirects write operations. Write access is completely forbidden and raises an exception. However, the restrictions affect only values that cross the border between the global execution environment and a predicate execution. Values that are defined and used in one side, e.g. local values, were not restricted. Write access to those values is fine.

Other approaches implement restrictions by filtering and rewriting untrusted code or by removing features that are either unsafe or that grant uncontrolled access. The Caja Compiler [29, 43], for example, compiles JavaScript code in a sanitized JavaScript subset that can safely be executed in normal engines. However, some static guarantees do not apply to code created at run time. For this reason Caja restricts dynamic features and adds run-time checks that prevent access to unsafe function and objects.

7 Conclusion

We presented TreatJS, a language embedded, dynamic, higher-order contract system for full JavaScript. TreatJS extends the standard abstractions for higher-order contracts with intersection and union contracts, boolean combinations of contracts, and parameterized contracts, which are the building blocks for contracts that depend on run-time values. TreatJS implements proxy-based sandboxing for all code fragments in contracts to guarantee that contract evaluation does not interfere with normal program execution. The only serious impediment to full noninterference lies in JavaScript’s treatment of proxy equality, which considers a proxy as an individual object.

The impact of contracts on the execution time varies widely depending on the particular functions that are under contract and on the frequency with which the functions are called.
While some programs’ run time is heavily impacted, others are nearly unaffected. We believe that if contracts are carefully and manually inserted with the purpose of determining interface specifications and finding bugs in a program, their run time will mostly be unaffected. But more experimentation is needed to draw a statistically valid conclusion.

## A Contracts in a Higher-order World

In addition to contracts already mentioned in the paper, TreatJS offers a wealth of further features included in its core or convenience API.

Let’s start off with defining a number of base contracts for later use.

```javascript
var typeNumber = Contract.Base(function (arg) {
    return (typeof arg) === 'number';
});

var typeBoolean = Contract.Base(function (arg) {
    return (typeof arg) === 'boolean';
});

var typeString = Contract.Base(function (arg) {
    return (typeof arg) === 'string';
});

var isArray = Contract.With({Array:Array}, Contract.Base(function (arg) {
    return (arg instanceof Array);
}));

var isUndefined = Contract.Base(function (arg) {
    return (arg === undefined);
});

var Any = Contract.Base(function (arg) {
    return true;
});
```

Analogous to `typeNumber`, the contracts `typeBoolean` and `typeString` check the type of their argument. Contract `isArray` checks if the argument is an array, `isUndefined` checks for `undefined`, and `Any` is a contract that accepts any value.

### A.1 Simple Function Contracts

To keep the contract system usable it is important that contract definitions are as short as possible. So, instead of defining a function contract in terms of an object contract, the simplest way to define a function contract is to give a sequence of contracts.

The function `SFunction` is the constructor for a simple function contract. Its arguments are contracts. If called with `n + 1` arguments for `n ≥ 0`, then the first `n` arguments are contracts for the first `n` function arguments and the last argument is the contract for the result. This contract constructor is sufficient for most functions that take a fixed number of arguments.

The following function contract is another simple function contract equivalent to the contract already defined in the paper (Line 21). The constructor function `SFunction` implicitly creates an object contract from its `n` arguments.

```javascript
Contract.assert(cmpUnchecked, Contract.SFunction(typeNumber, typeNumber, typeBoolean));
```
### A.2 Object and Method Contracts

A combination of object and function contracts is useful for specifying the methods of an object. The contract below is a fragment of such a specification. It states that the \textit{length} property is a number and that the \textit{foreach} property is a function that takes a number and any value to return \texttt{undefined}. The function stored in \textit{foreach} is to return \texttt{undefined}.

```
Contract.AObject(
    length:typeNumber,
    foreach:Contract.AFunction([Contract.AFunction([typeNumber, Any], isUndefined), isUndefined])
);
```

Apart from normal function contracts, \texttt{TreatJS} provides a \textit{method contract}. A method contract extends a function contract by a third portion, applied to the \texttt{this} reference. A similar extension is applied to dependent contracts.

```
Contract.AMethod([Contract.AFunction([typeNumber,Any],isUndefined)], isUndefined,isArray);
```

This fragment defined a contract for a \textit{foreach} method of an \texttt{array} object. The first two arguments are equivalent to the definition of a function contract. The third portion indicates that the \texttt{this} reference has to be an instance of \texttt{Array}.

The following contract now combines both contracts.

```
Contract.AMethod([Contract.AFunction([typeNumber,Any],isUndefined)], isUndefined, Contract.AObject({length:typeNumber}));
```

### A.3 Regular Expression Matching

An object contract maintains a mapping from property names to contracts. But, this mapping is inconvenient if more than one property match to the same contact. To simplify this, \texttt{TreatJS} also provides regular expression matching in object contracts.

Core object contracts are drawn from a mapping, that points property names to contracts. This mapping can either be a string map, which maps strings to contracts, or a regular expression map that contains pairs of a regular expression and a contract. When accessing a property the map checks the presents of the property’s name and returns the set of associated contracts.

```
```

### A.4 Reflection Contracts

Object contracts follow Reynolds [45] interface for a reference cell: each property is represented as a pair of a getter and a setter function. Both, getter and setter apply the same contract but on different portions.

However, property access and property assignment can be seen as a meta-level call. A \texttt{get} function accepts a target value and a property name and returns a value, whereas a \texttt{set}

---

\textsuperscript{15}Recall that \texttt{undefined} is a proper value in JavaScript. All functions that have no return value in fact return \texttt{undefined}. 

function accepts target object, a property name, and a value and returns another value. This corresponds to JavaScrip’s get and set trap as specified in its reflection API.

*TreatJS* enables to define reflection contract which apply directly to the corresponding operation. In detail, a reflection contract requires a function contract as argument which is applied to the corresponding trap.

The following examples demonstrated an get contract that checks whether the accessed property exists or not.

```javascript
var PropertyCheck =Contract.Constructor(function()) {
    var target = {};
    var getTarget = Contract.Base(function(arg) {
        return target = arg;
    });
    var checkProperty = Contract.Base(function(name) {
        return (name in target);
    });
    var any = Contract.Base(function() {
        return true;
    });
    return Contract.Get(Contract.AFunction([getTarget, checkProperty], any));
};
```

The constructor first defines a base contract that stores the target object, whereas the second base contracts checks for an undefined property.

Other reflection contracts can be built in the same way.

### A.5 Boolean Combination of Contracts

Beyond base, function, and object contracts, *TreatJS* provides the standard boolean operators on contracts: conjunction (And), disjunction (Or), and negation (Not) with the obvious meanings. The result of a boolean operator on contracts is again a contract that may be further composed.

The following example demonstrates boolean operators with base contracts. The contracts should be self-explanatory and none of them should fail.

```javascript
var isPositive = Contract.Base(function (arg) {
    return (arg > 0);
});
Contract.assert(1, Contract.And(typeNumber, isPositive));
Contract.assert(‘k’, Contract.Or(typeNumber, typeString));
Contract.assert(1, Contract.Not(isUndefined));
```

Boolean operators are not really exciting for base contracts as they could be pushed into the predicates. However, their use improves modularity and they open interesting possibilities in combination with function and object contracts.

For example, we may combine the *lengthTwo* contract with the contract on *cmp* to further sharpen the contract for a function like *cmp*. This contract guarantees that a function is only ever invoked with exactly two arguments, that these arguments must be numbers, and that the function must return a boolean.

```javascript
var lengthTwo = Contract.Base(function (args) {
    return (args.length == 2);
};
```
48 });
49 var cmpNumbers = Contract.AFunction([typeNumber, typeNumber], typeBoolean);
50 Contract.And (lengthTwo, cmpNumbers);

Boolean operators may also express alternatives. A contract for cmp that reflects that JavaScript’s < operator also compares strings would look as follows.

51 var cmpStrings = Contract.AFunction([typeString, typeString], typeBoolean);
52 Contract.Or(cmpNumbers, cmpStrings);

The disjunction of two function contracts requires that each call site fulfills one of the constituent contracts. As both functions contracts promises to return a value that satisfies typeBoolean we can alternately lift the disjunction to the arguments.

53 Contract.Function(Contract.Or(Contract.AObject([typeNumber, typeNumber]),

Contract.AObject([typeString, typeString])), typeBoolean);

Using the conjunction of these two function contracts would always signal a violation because no argument fulfills typeNumber and typeString at the same time.

For conjunctions blaming is easy because all parts of the conjuncted contracts have to hold. For disjunctions the context is to blame if it does not satisfy one of the disjuncts. If at least one domain portion fits but the results does hold for one of the corresponding range contracts blame is assigned to the subject.

At first glance, a negated function contract seems to be pointless, because negation could be eliminated by pushing it into the predicates of the base contracts. But, again, there are modularity and reusability benefits and the use of negation can give rise to succinct contracts.

Consider the contract typeNumber→isPositive. Asserting it to a function requires that typeNumber accepts the argument value and isPositive accepts the return value. Otherwise, a contract violation is signaled. However, the programmer may have a much weaker guarantee in mind. The only useful guarantee may be that if the argument satisfies typeNumber, then isPositive accepts the return value. A negated function contract expresses such a (weak) guarantee succinctly.

54 Contract.Not(Contract.SFunction(typeNumber, Contract.Not(isPositive)));

The inner contract accepts only if the argument is a number, but the return value is not greater than zero. Thus, its negation has the desired behavior. Of course, such a contract could be written without a negated function contract, but it is much less perspicuous.

55 Contract.Or(Contract.SFunction(typeNumber, isPositive), Contract.SFunction( Contract.Not(typeNumber), Any));

However, the possibility to compose contracts arbitrarily without restriction enables a programmer to build higher-level connections in top of the boolean combinators e.g. a conditional (implication), a biconditional, a exclusive disjunction, a alternative denial, and a joint denial.

A.6 Weak and Strict Contracts

Let’s recapitulate the two kinds of contracts assigned to the cmp function.

56 Contract.And (lengthTwo, cmpNumbers);

The first one checks that the function is called with exactly two arguments, where the second indicates that both arguments are of type number. This combination is required to get a strict interpretation of the specified contract.
Now, we have to admit that a function contract like `Contract.SFunction(IsNumber, IsNumber, IsBoolean)` gives a weak interpretation. If the contracted function only takes use of the first argument, the second would never be checked. This makes it possible that the function is called with a pair of type `(Num, String)` without raising a contract violation. This is because the domain contracts are mapped to the arguments array whose check is only when accessing an element (similar to an object contract).

In JavaScript it is possible to call a function with more or less arguments than specified in a function. Each argument can be addressed by accessing the arguments array directly. Because the given interpretation is neither right nor wrong, `TreatJS` makes it possible to differ between a weak and a strict interpretation of object contracts. This can be done by setting a flag when defining the object contract.

```javascript
var weak = Contract.AObject({a:typeNumber,b:typeString,c:typeBoolean}, false);
var strict = Contract.AObject({a:typeNumber,b:typeString,c:typeBoolean}, true);
```

Forcing the object contract to be strict, each specified property gets immediately checked when the contract is asserted.

### A.7 Sandboxing Contracts

Consider the following base contract where the programmer carelessly omitted the `var` keyword in the predicate.

```javascript
var faultyLengthTwo = Contract.Base(function (arg) {
    length = arg.length;
    return (length===2);
});
```

If we assert `faultyLengthTwo` to a value, the predicate attempts to write to the global variable `length`. But the sandbox intercepts this write operation and throws an exception.

Passing a function into the sandbox poses a special problem because the function may perform side effects on its free variables. The sandbox removes these free variable bindings so that any use of `faultyLengthTwo` signals a violation.

### A.8 Parameterized Contracts

Because sandboxing restricts any access to the outside world, `TreatJS` provides a `With` contracts that binds values and a contract constructor that defines contracts apart from the normal program execution.

This setup enables us to build parameterized contracts by substituting parameters inside of base contracts.

Let’s recap the `lengthTwo` contract. Using `With` enables to exclude the targets `length` and to reuse the base contract with various objective.

```javascript
var hasLength = Contract.Base(function(arg) {
    return (arg.length===length);
});
var lengthTwo = Contract.With({length:2}, hasLength);
var lengthThree = Contract.With({length:3}, hasLength);
```

The following example shows a contract constructor that builds a base contracts to which checks the length property of its argument. The constructor gives an alternative notation to the contract in Line 63.
var Length = Contract.Constructor(function(length) {
  return Contract.Base(function(arg) {
    return (arg.length === length);
  });
});

To obtain the actual contract we need to apply the constructor to some parameters
with the method Contract.construct(Length, 2) or we gather the constructor's construct
method, which is referred by its construct property, and use this as a parameterisable
contract.

var LengthTwo = Length.construct(2);
var LengthThree = Length.construct(3);

The constructor function takes one parameter, length, builds a base contract that checks
the length property of an object, and returns an appropriate contract.

### A.9 Contract Abstraction

Let's consider another use of constructors, contract abstraction. Contract abstraction happens
if one asserts a constructor directly to a value instead of applying a value and deriving a
contract from it.

Let's recap the cmp function described in the paper. The function may accept values
of type number, string, or boolean as argument and guarantees to return a boolean value.
Instead of building the intersection between different alternatives one can build an contract
abstraction that first needs to be applied with a value that specifies the input’s type.

First, let's define an appropriate constructor.

```javascript
var Cmp = Contract.Constructor(function(type) {
  var typeOf = Contract.Base(function(arg) {
    return type === (typeof arg);
  });
  var typeBoolean = Contract.Base(function(arg) {
    return (typeof arg) === 'boolean';
  });
  return Contract.AFunction([typeOf, typeOf], typeBoolean);
});
```

The contractor abstracts the input type and returns a function contract with respect to the
constructor’s argument.

Instead of building a contract from such a constructor, one can assert the contract to a
value. Constructors are contracts and can be asserted to values as contracts are.

```javascript
var cmpAbs = Contract.assert(cmp, Cmp);
```

cmpAbs is an abstraction of the cmp function. To unroll the abstraction we have to call
cmpAbs with the arguments required by the constructor.

```javascript
var cmpNumber = cmpAbs('number');
var cmpString = cmpAbs('string');
```

Here, cmpNumber (cmpString) is a contracted versions of cmp that accepts number (string)
values as argument. The following code snipped shows how to use the abstraction in one
step.
Instead of passing around type information, constructors can abstract over contracts. The following example shows another abstraction for `cmp`.

```javascript
var Cmp2 = Contract.Constructor(function(typeOf) {
    var typeBoolean = Contract.Base(function(arg) {
        return (typeof arg) === 'boolean';
    });
    return Contract.AFunction([typeOf, typeOf], typeBoolean);
});
var cmpAbs2 = Contract.assert(cmp, Cmp2);
var result = cmpAbs2(typeNumber)(1,2);
```

### A.10 Recursive Contracts

Yet another use of contract constructors is recursion. Recursive contracts are similar to constructors, but instead of building an abstraction the constructor function is pending and evaluates to a contract when asserted. Then, the recursive contract is given as argument to the constructor function.

The following example defines a recursive contract for a linked list so that the `next` property satisfies the same contract as the current element.

```javascript
var LinkedListCtor = Contract.SRecursive(function ctorFun(recursive) {
    return Contract.Object({
        val:IsNumber,
        next:recursive
    });
});
```

The code fragment defines a constructor based on a named function `ctorFun`. Each read access to the `next` property of a contracted object would assert a new instance of itself to return a contracted object.

### A.11 Consistency of Values

A contract constructor may also verify that a value does not change during a function call. The following example illustrates how to check that `arg[p]` does not change. The constructor stores a copy of `arg[p]` and the returned base contract compares the copy with the current value.

```javascript
var NotChangedCtor = Contract.Constructor(function(target) {
    var v = target[p];
    return Contract.Base(function (arg) {
        return (v === target[p]);
    });
});
```

### A.12 Implicit Assertions

Naturally, each predicate is an implicit conjunction of different properties. Consider the base contracts `NonEmpty` and `NotEmpty`, both of which check the length of an array.
\textbf{Expression} \quad \exists e, f, g ::= e \mid x \mid E \mid A \mid \text{op}(e, f) \mid \lambda x. e \mid e[f] \mid e[f] = g \mid e@f f

\textbf{Contract Expressions} \quad \exists \mathcal{E}, \mathcal{F} ::= \lambda x. e \mid \mathcal{E} \rightarrow \mathcal{F} \mid x \rightarrow A x \mid \mathcal{E} \cap \mathcal{F} \mid \mathcal{E} \cup \mathcal{F} \mid \mathcal{E} \land \mathcal{F} \mid \mathcal{E} \lor \mathcal{F} \mid \neg \mathcal{E} \mid M

\textbf{Contract} \quad \exists \mathcal{C}, \mathcal{D} ::= I \mid Q \mid \mathcal{C} \cap \mathcal{D} \mid \mathcal{C} \cup \mathcal{D} \mid \mathcal{C} \land \mathcal{D} \mid \mathcal{I} \lor \mathcal{C}

\textbf{Immediate} \quad \exists I, J ::= \lambda x. e \mid \neg I

\textbf{Delayed} \quad \exists Q, R ::= \mathcal{C} \rightarrow \mathcal{D} \mid x \rightarrow A x \mid \mathcal{M} \mid Q \cap \mathcal{R} \mid Q \lor \mathcal{R} \mid \neg Q

\textbf{Abstraction} \quad \exists A ::= \Lambda \mid \mathcal{C}. E

\textbf{Mapping} \quad \exists M ::= \emptyset \mid \mathcal{M}[c \mapsto \mathcal{E}]

\begin{figure}[h]
\begin{lstlisting}
var NonEmpty = Contract.Base(function (arg) {
  return (arg.length>0);
});

var NotEmpty = Contract.Base(function (arg) {
  return (arg.length!==0);
});
\end{lstlisting}
\caption{Syntax of $\lambda_{J}^{Con}$.}
\end{figure}

Described in detail, both contracts require that the given argument is an object \textit{and} the comparison of the arguments property \texttt{length} and the value 0 results in true. The comparison produces \texttt{true}, \texttt{false}, or \texttt{undefined}, where \texttt{undefined} indicates that at least one operand is \texttt{NaN}. But, the meaning of the contracts \texttt{NonEmpty} and \texttt{NotEmpty} is different. Both check that the arguments length is not zero. But, if the given argument does not have a length property or the property is, for example, a string value, the predicate in \texttt{NotEmpty} holds whereas \texttt{NonEmpty} fails.

\section{JavaScript Core Calculus with Contracts}

This section introduces $\lambda_{J}^{Con}$, a call-by-value lambda calculus with objects and object proxies that serves as a core calculus for JavaScript, inspired by previous work \cite{31, 33, 37, 50}. It defines its syntax and describes its semantics informally.

\subsection{Core Syntax of $\lambda_{J}^{Con}$}

Figure 4 defines the syntax of $\lambda_{J}^{Con}$. A $\lambda_{J}^{Con}$ expression is either a constant, a variable, a contract expression, an contract abstraction, an operation on primitive values, a lambda abstraction, an application, a creation of an empty object, a property read, a property assignment, or a contract assertion that performs contract monitoring. Variables $x, y$ are drawn from denumerable sets of symbols and constants $c$ include JavaScript’s primitive values like numbers, strings, booleans, as well as \texttt{undefined} and \texttt{null}.

The assert expression, $e@f$, is new to our calculus. It evaluates expression $f$ to a contract $\mathcal{C}$ and attaches $\mathcal{C}$ to the value of expression $e$. 
B.2 Contract normalization

Contracts $C, D$ are drawn from a set of contract expressions $E, F$ that also contain top-level intersections of contracts. But, contract monitoring first normalizes contracts into a canonical form before it starts their enforcement.

Normalization factorizes a contract into its immediate part and its delayed part. The immediate part consists of flat contracts (viz. nonterminal $I$ and $J$) that are subject to intersection whereas the delayed part is an intersection of function contracts (viz. nonterminals $Q$ and $R$). Unions are pulled out of intersections by applying the distributive law suitably. Negations apply DeMorgan’s Law until the negations reaches an immediate or delayed contract.

B.3 Contracts and Contract Assertion

A canonical contract $C$ is either an immediate contract $I$, a delayed contract $Q$, an intersection between two contracts $I \cap C$, or an union $C \cup D$, or a boolean combination of contracts: conjunction $C \land D$, disjunction $I \lor C$, or negation $\neg I$ or $\neg Q$.

Contract distinguish immediate contracts $I$ that may be checked right away when asserted to a value and delayed contracts $Q$ that need to be checked later on.

The base contract $\lambda x.e$ is immediate. It consists of a function $\lambda x.e$ that is interpreted as a predicate on $x$. Asserting base contract to a value applies the function to the value and signals a violation unless the function returns a truthy result. Otherwise, the assertion returns the value.

The evaluation of the predicate’s body $e$ takes place in a sandbox. The sandbox ensures noninterference with the actual program code by stopping evaluation of the predicate if there is an attempt to modify data that is visible outside the contract.\(^{16}\)

A delayed contract $Q$ is either a function contract $C \to D$, a dependent contract $x \to A x$, an object contract $M$, an intersection of delayed contracts $Q \cap R$, or a disjunction of delayed contracts $Q \lor R$.

The delayed contracts include intersections and disjunctions because each application of a function with such a contract has to check all parts of the contract.

A function contract $C \to D$ is built from a pair of contracts, one for the domain ($C$ is asserted to the argument) and one for the range ($D$ is asserted to the result) of a function.

A dependent contract $x \to A x$ is a kind of function contract. Applying a function contracted to some value $v$ applies the abstraction $A$ to $v$ and asserts the resulting contract to the result of applying the original function to $v$.

An object contract $M$ is a mapping from property names to contracts. The contract for property $c$ is expected to hold for property $c$ of the contracted object. In practice, $c$ is a string.

A contract abstraction $\Lambda x.C$ is not a contract by itself, but abstracts the parameter $x$ that is bound in contract $C$. Dependent contracts and constructor applications rely on abstractions to substitute run-time values for $x$ in $C$.

B.4 Constraints

Precise blaming of violators gives a useful feedback to the developers. However, signaling a violation depends on a combination of failures and successes in different contracts and is not

\(^{16}\) The sandbox cannot ensure termination of the predicate, of course.
necessarily the last failing contract.

This connection is modeled by so-called constraints $\kappa$ (see Figure 5). They are tied to a particular contract assertion and link each contract to its next enclosing boolean operation, at the top-level, its assertion.

Constraints contain blame identifiers $b$, where we distinguish blame labels $\ell$ that occur in source programs from internal blame variables $\iota$. Each blame identifier is related to one specific contract occurrence in the program; there is at least one identifier for each contract occurrence and there may be multiple identifiers for delayed contracts (e.g., function contracts).

Each blame identifier $b$ is associated with a record that defines the blame assignment for the contract occurrence related to $b$. This record contains two fields, subject and context. The intuitive meaning of the fields is as follows. If the subject field is false, then the contract fails blaming the subject (i.e., the value to which the contract is asserted). If the context field is false, then the contract fails blaming the context (i.e., the user of the value to which the contract is asserted).

A constraint is either the base constraint $b \leftarrow v$ that signals the outcome $v$ of a base contract to blame identifier $b$ or it chains the outcomes of the constituents of a contract to the outcome of the contract in $b$.

The fields in the outcome range over $\mathbb{B}_4$, the lattice underlying Belnap’s four-valued logic. Belnap [6] introduced a logic intended to deal with incomplete or inconsistent information. The set $\mathbb{B}_4 = \{\bot, f, t, \top\}$ of truth values models a lattice illustrating accumulated knowledge about the truth of a proposition. Thus, a truth value may be considered as the set of classical truth values $\{\text{true}, \text{false}\}$ that have been observed so far for a proposition. For instance, contracts are counted ad $\bot$ before they are evaluated and $\top$ signals potentially conflicting outcomes of repeated checking of the same contract.

The set $\mathbb{B}_4$ naturally forms a powerset lattice, the approximation lattice, with the subset ordering on the underlying sets, which we denote by $\subseteq$, and an ordering by truth, the logical lattice. We use the symbols $\neg$, $\land$, and $\lor$ for the connectives on $\mathbb{B}_4$; they are generalizations of the standard connectives on truth. Meet and join under $\subseteq$ are denoted by $\cap$ and $\cup$.

Boolean terms are standard, but their interpretation is in terms of $\mathbb{B}_4$. Similar to other logics, conjunction and disjunction have “shortcuts” that enable them to fail (respectively, succeed) even if one of the operands is still $\bot$. More informations about boolean connectives in a bilattice-based logic can be found in [40].

Contract monitoring happens in the context of a constraint set $\varsigma$ which collects constraints during evaluation.

A solution $\mu$ of a constraint set $\varsigma$ is a mapping from blame identifiers to records of elements of $\mathbb{B}_4$, such that all constraints are satisfied. Formally, we specify the mapping by\footnote{We write $\emptyset$ for the set ranged over by metavariable $b$.}

$$
\mu \in (\emptyset) \times \{\text{subject, context}\} \to \mathbb{B}_4
$$
and constraint satisfaction by a relation \( \mu \models \zeta \), which is specified in Figure 6.

In the premisses, the rules apply a constraint mapping \( \mu \) to boolean expressions over constraint variables. This application stands for the obvious homomorphic extension of the mapping.

Rule CS-EMPTY states that every mapping satisfies the empty set of constraints. Rule CS-UNION states that the union of constraints corresponds to the intersection of sets of solutions.

The rule CT-FLAT treats the constraint generated for the outcome \( b \) of the predicate of a flat contract. The function \( \tau(\cdot) : (\mathcal{B}_4) \to \mathcal{B}_4 \) translates outcomes to truth values. It corresponds to JavaScript’s idea of truthy and falsey. It is defined by

\[
\tau(b) := \begin{cases} 
  t, & b \in \{\bullet, false, undefined, null, NaN, ""\} \\
  t, & \text{otherwise}
\end{cases}
\]

where \( \bullet \) symbolises an exception, that counts as false, too.

The rule CT-FUNCTION determines the blame assignment for a function contract \( b \) from the blame assignment for the argument and result contracts, which are available through \( \iota_1 \) and \( \iota_2 \). A function does not fulfill contract \( b \) if it does not fulfill its obligations towards its argument \( \iota_1.\text{context} \text{ or} \) if the argument fulfills its contract, but the result does not fulfills its contract. The first part arises for higher-order functions, which may pass illegal arguments to their function-arguments. The second part corresponds to partial correctness of the function with respect to its contract.

A function’s context (caller) fulfills the contract if it passes an argument that fulfills its contract \( \iota_1.\text{subject} \text{ and} \) it uses the function result according to its contract \( \iota_2.\text{context} \). The second part becomes non-trivial with functions that return functions.

Rule CT-SET determines the blame assignment for an object contract at \( b \) from the blame assignment for the property contract at \( \iota \). An object (subject) does not fulfill an object contract if it returns a value that does not fulfill the contract. An object’s context (caller) does not fulfills the contract if it does not uses the objects return according to its contract or is assigns an illegal value to a contracted property.

The outcome of read access on contracted properties is directly related to \( b \) and do not need a special constraint. For write access, it is up to the context to assign a value according to the contract. Constraint \( b \triangleleft \iota \) gives the responsibilities of \( \iota.\text{subject} \) to the context \( b.\text{context} \).

The rule CT-INTERSECTION determines the blame assignment for an intersection contract at \( b \) from its constituents at \( \iota_1 \) and \( \iota_2 \). A subject fulfills an intersection contract if it fulfills both constituent contracts: \( \iota_1.\text{subject} \triangleleft \iota_2.\text{subject} \). A context, however, only needs to fulfill one of the constituent contracts: \( \iota_1.\text{context} \triangleleft \iota_2.\text{context} \).

Dually to the intersection rule, the rule CT-UNION determines the blame assignment for a union contract at \( b \) from its constituents at \( \iota_1 \) and \( \iota_2 \). A subject fulfills a union contract if it fulfills one of the constituent contracts: \( \iota_1.\text{subject} \triangleleft \iota_2.\text{subject} \). A context, however, needs to fulfill both constituent contracts: \( \iota_1.\text{context} \triangleleft \iota_2.\text{context} \), because it does not known which contract is fulfilled by the subject.

The rules CT-AND, CT-OR, CT-NEGATION show blame assignment for the classical boolean connectives. A subject fulfills a conjunction contract at \( b \) if it fulfills both contracts at \( \iota_1.\text{subject} \) and \( \iota_2.\text{subject} \) in case the context fulfills its obligations. The context also needs to fulfill both contracts: \( \iota_1.\text{context} \) and \( \iota_2.\text{context} \).

In the same way, a subject fulfills a disjunction contract at \( b \) if it fulfills at least one side of the disjunction. The context might choose to fulfill at \( \iota_1.\text{context} \) or \( \iota_2.\text{context} \).

**Figure 6** Constraint satisfaction.
For negations, a subject fulfills a negation contract at $\flat$ if it does not fulfill the contract at $\iota$. subject in case the context fulfills its obligation. The context does always fulfill its obligation.

Inspection of constraint satisfaction and monotonicity of the logical operations on $\mathcal{B}_4$ shows that every finite set of constraints corresponds to a monotone mapping on a complete lattice of finite height. By the Knaster-Tarski theorem, each constraint set $\varsigma$ has a least solution

$$[\varsigma] \in (\emptyset) \times \{\text{subject, context}\} \rightarrow \mathcal{B}_4$$

such that $[\varsigma] \models \varsigma$ and $[\varsigma] \subseteq \mu$ for all $\mu \models \varsigma$, which can be computed as the least fixpoint of the monotone mapping. Hence, we define the semantics of a constraint set $[\varsigma]$ as this least fixpoint.

To determine whether a constraint set $\varsigma$ is a blame state (i.e., whether it should signal a contract violation), we need to check whether the semantics $[\varsigma]$ maps any source level blame label $\ell$ to false.

▶ **Definition 1 (Blame State).** $\varsigma$ is a blame state iff $[\varsigma]^{-1}(\{f, \top\}) \cap (\emptyset \times \{\text{subject, context}\}) \neq \emptyset$.

▶ **Lemma 2.** The blame state predicate is a monotone mapping from $(\emptyset) \times \{\text{subject, context}\} \rightarrow \mathcal{B}_4$ to $\{\text{false, true}\}$ ordered by $\text{false} < \text{true}$.

## C Contract Monitoring

This section presents the formal semantics of $\lambda_C^{\text{Con}}$ including evaluation and contract enforcement. The formalization employs pretty-big-step semantics [12] to model side effects and the signaling of violations while keeping the number of evaluation rules manageable.

### C.1 Semantic Domains

Figure 7 defines the semantic domains of $\lambda_C^{\text{Con}}$.

Its main component is a store that maps a location $l$ to an object $o$, which is either a native object (non-proxy object) represented by a triple consisting of a dictionary $d$, a potential function closure $f$, and a value $v$ acting as prototype or a proxy object. A dictionary $d$ models the properties of an object. It maps a constant $c$ to a value $v$. An object may be a function in which case its closure consists of a lambda expression $\lambda x.e$ and an environment $\rho$ that binds the free variables. It maps a variable $x$ to a value $v$. A non-function object is indicated by $\square$ in this place.
A proxy object is a single location controlled by a proxy handler $h$ that mediates the access to the target location. For simplification, we represent handler objects by their meta-data. So, a handler is either a sandbox handler that enforces write-protection (viz. by an single secure environment $\hat{\rho}$) or a contracted object (viz. by an environment $\hat{\rho}$, a callback identifier $\♭$, and a delayed contract $Q$).

The syntax do not make proxies available to the user, but offers an internal method to wrap objects. A value $v$ is either a constant $c$, a location $l$, or a contract value, which is either a contract $C$ or a contract abstraction $A$ in combination with a sandbox environment.

For clarity, we write $\hat{v}, \hat{u}, \hat{w}$ for wrapped values that are imported into a sandbox and $\hat{\rho}$ for a sandbox environment that only contains wrapped values.

### C.2 Evaluation of $\lambda^C_J$

A pretty-big-step semantics introduces intermediate terms to model partially evaluated expressions (Figure 8). An intermediate term is thus an expression where zero or more top-level subexpressions are replaced by their outcomes, which we call behaviors. A behavior $b$ is either a value $v$ or an exception $\bullet$, which may be associated with a contract or a sandbox violation. Terms are constructed with a specific evaluation order in mind so that the exception handling rules that propagate exceptions to the top-level are easy to state.

The evaluation judgment is similar to a standard big-step evaluation judgment except that its input ranges over intermediate terms and its output is a behavior: It states that evaluation of term $t$ with constraint set $\varsigma$, initial store $\sigma$, and environment $\rho$ results in a new constraint set $\varsigma'$, final heap $\sigma'$, and behavior $b$.

$$\rho \vdash \langle \varsigma, \sigma, t \rangle \Downarrow \langle \varsigma, \sigma', b \rangle$$

Figure 9 and 10 defines the standard evaluation rules for expressions $e$ in $\lambda^C_J$. The inference rules for expressions are mostly standard. Each rule for a composite expression evaluates exactly one subexpression and then recursively invokes the evaluation judgment to continue. Once all subexpressions are evaluated, the respective rule performs the desired operation.

The corresponding straightforward error propagation rules are disjoint to the remaining rules because they fire only if an intermediate term contains an exception. The rules set in Figure 11 defines error handling.

#### C.2.1 Contract Construction

Contract monitoring happens in the context of a secure sandbox environment to preserve noninterference. So a contract definition (contract abstraction) will evaluate to a contract closure containing the contract (the abstraction) together with an empty environment or together with a sandbox environment $\hat{\rho}$ when defining the contract (the abstraction) inside of a sandbox environment. Figure 12 contains its inference rules.
<table>

\[ \overline{\rho}[x \mapsto \hat{w}] \vdash \varsigma', \sigma', \mathcal{C} \Downarrow \varsigma', \sigma', b \]

\[ \rho \vdash \varsigma, \sigma, (\overline{\rho}, \Lambda x. \mathcal{C})(w) \Downarrow \varsigma', \sigma', b \]

\[ \text{Figure 12} \text{ Contract Construction rules for } \lambda_j^{\text{com}}. \]

Constructor application (Rule \text{CONSTRUCT}) starts after the first expression evaluates to a contract closure and the second expression evaluates to a value. It wraps the given value and evaluates the contract \mathcal{C} in the sandbox environment after binding the sandboxed value \hat{w}.

C.2.2 Contract Assertion

It remains to define contract assertion (Figure 13).

Rule \text{Assert} applies after the first subexpression evaluates to a value and the second subexpression evaluates to a contract-value. It triggers the evaluation of contract \mathcal{C} in an sandbox environment \overline{\rho}.

Asserting a base contract to any value wraps the value to avoid interference and evaluates the predicate after binding the wrapped value. Finally, a new constraint is attached with the result of the predicate.

Once a base contract evaluates to a value (Figure 14) the constraint state is checked whether a violation can be signaled.

Rule \text{Assert-DelayedContract} asserts a delayed contract to an object. It wraps its location in a proxy together with the current sandbox environment, the associated blame identifier, and the contract itself. It is an error to assert a delayed contract to a primitive value.

Asserting an intersection-contract, an union-contract, or an boolean combination asserts the first subcontract to the value before it asserts the second subcontract to the resulting behavior. These contract evaluations create a new constraint that contains the corresponding operator, respectively.

C.2.3 Application, Read, and Assignment

Function application, property read, and property assignment distinguish two cases: either the operation applies directly to a non-proxy object or it applies to a proxy. If the target of the operation is not a proxy object, then the usual rules apply.

Figure 15 contains the inference rules for function application and property access for the non-standard cases.

If the target object is a proxy that carries a function contract, then the domain contract \mathcal{C} is attached to the argument. Next, function application continues by passing the input value to the proxy’s target location \text{l’}. After completion, the range contract \mathcal{D} is applied to the function’s result.
Figure 13 Inference rules for contract assertion.

\]
\[
\rho \vdash \varsigma, \sigma, l[c] = v \downarrow \varsigma', \sigma', v
\]

Figure 15 Inference rules for function application, property read, and property assignment.
The assertion of both contracts takes place inside the sandbox environment $\hat{\rho}$ stored in the proxy. A new constraint with two fresh variables indicates that both parts have to hold. In case of a dependent contract attached to a function, function application proceeds by passing the input value to the proxy’s target location. Next, the original function argument gets passed to the contract constructor where the value gets wrapped to be acceptable in the sandbox environment. Finally, the wrapped input is bound in the sandbox environment and the contract assertion proceeds on the function’s result.

A property read on a contracted object has two cases depending on the presence of a contract for the accessed property. If a contract exists, then the contract is attached to the value after reading it from the target $l'$ of the proxy. Otherwise, the value is simply read from the target. The assertion of a contract happens in the context of the included constraint.

A property write on a contracted object continues with the operation on the target location $l'$ after the contract is attached to the value. Therefore, the adherence to a contract is also checked on assignments, but the check happens in the context of a fresh constraint that inverts the responsibilities.

### C.2.4 Sandbox Encapsulation

The sandbox encapsulation (Figure 16) distinguishes several cases. A primitive value, a contract value, and a contract abstraction value is not wrapped.

To wrap a location that points to a non-proxy object, the location is packed in a fresh proxy along with the current sandbox environment. This packaging ensures that each further access to the wrapped location has to use the current environment.

In case the location is already wrapped by a sandbox proxy or the location of a sandbox
proxy gets wrapped then the location to the existing proxy is returned. This rule ensures that an object is wrapped at most once and thus preserves object identity inside the sandbox.

If the location points to a contracted object, the wrap operation continues with the target \( l' \), before adding all contract from the contracted object.

The application of a wrapped function proceeds by unwrapping the function and evaluating it in the sandbox environment contained in the proxy. The function argument and its result are known to be wrapped in this case.

A property read on a sandboxed location continues the operation on the target and wraps the resulting behavior. An assignment to a sandboxed object is not allowed, thus it signals a sandbox violation.
